EECE 5644 Homework 3

Dhanush Balakrishna

Question 1

For this problem many multilayer perceptron (MLP) were used to approximate class label posteriors. Minimum average cross-entropy loss was used to train the MLP, and the trained models were then used to approximate a MAP classification rule to achieve minimum probability of error on a validation dataset.

For this exercise a 3-dimensional real-values random vector x was generated from 4 classes with uniform priors and Gaussian class conditional pdfs. The distributions used are shown below.

```
P(L=l) = 0.2, for l = [0,1,2,3].
```

```
m0= [2.5 2.5 0], C0= [1.00 0.01 0.01, 0.01 1.02 0.03, 0.01 0.03 1.06]

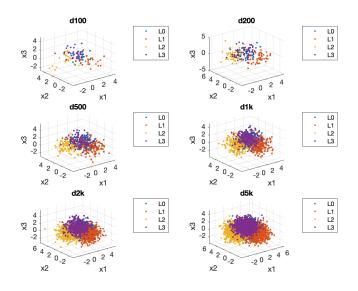

m1= [2.5 0 0], C1= [1.05 0.04 0.01, 0.04 1.04 0.01, 0.01 0.01 1]

m2= [0 2.5 0], C2=[1.06 0.08 0.05, 0.06 1.05 0.07, 0.06 0.05 1.05]

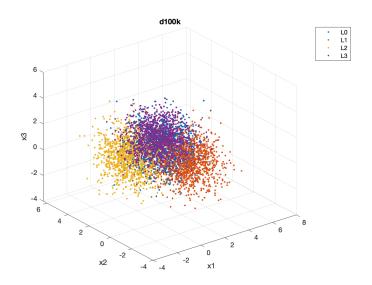

m3= [0 0 2.5], C3=[1.03 0.05 0.03, 0.03 1.05 0.04, 0.02 0.03 1.02]
```

A 2-layer MLP with one hidden and one output later was specified and implemented. The output layer was a "softmax" function as is the default for the MATLAB "patternnet" function that was implemented. Softmax function is a more generalized logistic activation function which is used for the multiclass classification. Softmax ensure all outputs are positive and add up to 1. The best number of perceptrons for your custom problem will be selected using cross-validation. Additionally, in the problem a smooth- ramp style activation function was activated . A sigmoid function can cause a neural network to get stuck at the training time. RelLu is half rectified from bottom and is a monotonic function.

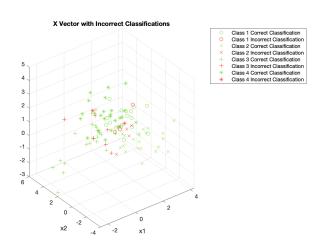

Below are the figures for training datasets with 100, 200, 500, 1000, 2000, and 5000 samples were generated and validation of test dataset with 100,000 samples was generated.

Classification of 100k Samples

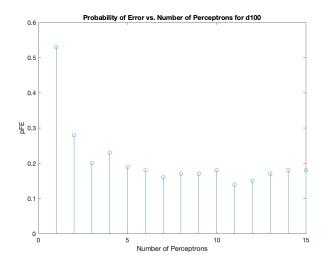

For each training dataset 10-fold cross validation was performed to determine the optimal amount of perceptron for the MLP model. In 10k fold cross validation would perform the fitting procedure a total of ten times, with each fit being performed on a training set consisting of 90% of the total training set selected at random, with the remaining 10% used as a holdout set for validation . The optimal number was the one that resulted in the minimum probability of error across the cross validation runs. Once the number of perceptron was selected a final model was then trained on the entire training dataset. Finally, this trained model was evaluated using the test dataset and the probability of error was calculated as the metric of model performance.

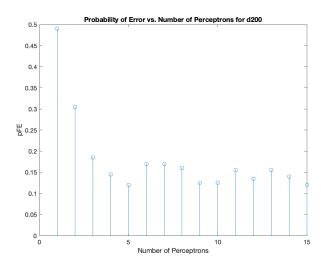

Below figure shows the results of this procedure. As can be seen in the plot, the overall probability of error is well correlated with the size of the training dataset. As the size of the dataset increases the probability of error decreases and approaches the optimal probability of error as estimated using the true pdf of the underlying data. This demonstrates that as the quantity of training data increases the model estimate can be improved resulting in more accurate classifications.

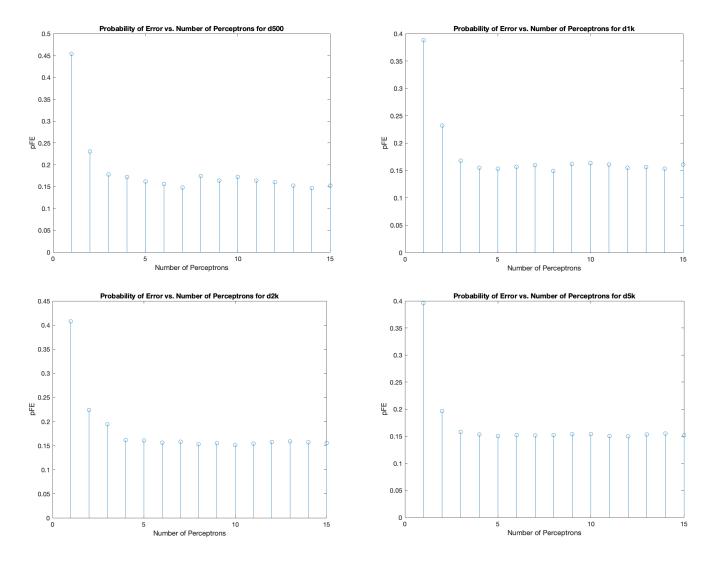

Probability of Error vs. Number of Data Points

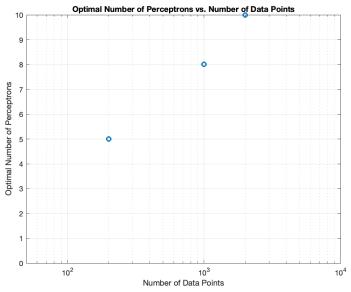

Probability of Error for various test datasets:

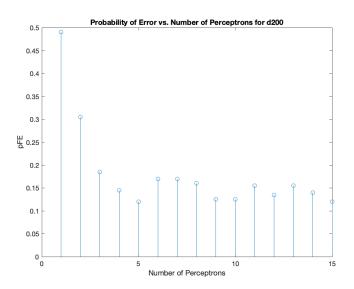

Below shows a plot of the optimal number of perceptrons versus the number of data points in a dataset. Except for the data point for the 1000-point training set the optimal number of perceptron appears to increase as the size of the training dataset increases. This was expected since as the size of the dataset increases the complexity of the model can also increase. More data means more features than can be modelled and therefore model complexity increases. When the model is trained much, it might reflect the incorrect probabilities too . Therefore, the training of the model is done in such a way that it does not sows the noise and inappropriate probabilities .

Below shows a plot of the cross-validation results for the 200-sample training dataset. In the plot the probability of error is shown as a function of the number of perceptrons. The probability of error starts very large for a single perceptron and then rapidly decreases as the number of perceptron increases. A minimum is identified at 11 and the probability error slowly tends to alter from fmin to max as the number of perceptron is increased. While the optimal number of perceptron varied between training datasets the overall relationship between the probability of error and the number of perceptron generally followed this pattern.

Probability errors are obtained as below: They lie in the range of 10-20%. The gaussian mixtures is selected in such a way that it lies between the 10-20%.

Optimal pFE, N=100: Error=9.00%

Optimal pFE, N=200: Error=14.50%

Optimal pFE, N=500: Error=14.40%

Optimal pFE, N=1000: Error=14.90%

Optimal pFE, N=2000: Error=15.30%

Optimal pFE, N=5000: Error=14.78%

Optimal pFE, N=100000: Error=14.69%

NN pFE, N=100: Error=18.90%

NN pFE, N=200: Error=16.44%

NN pFE, N=500: Error=15.60%

NN pFE, N=1000: Error=15.23%

NN pFE, N=2000: Error=15.00%

NN pFE, N=5000: Error=14.90%

As observed the error probability decreases with the increase in the number of samples . NN is the practically obtained probability errors .

Question 2:

Given question consist of the Gaussian Mixture Model as the true probability density function for 2- dimensional real-valued data synthesis. This GMM is having 4 components with different mean vectors, different covariance matrices, and different probability for each Gaussian to be selected as the generator for each sample.

Mean is given as : [-10 10 10 -10;10 10 -10 -10]

Covariances of 2-D matrix is given as:

Covariance $1 = [20 \ 1; 10 \ 3]$.

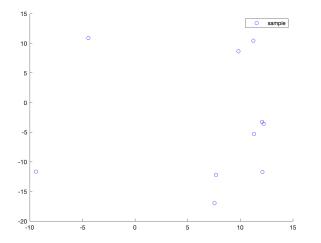

Covariance $2 = [7 \ 1; 1 \ 2].$

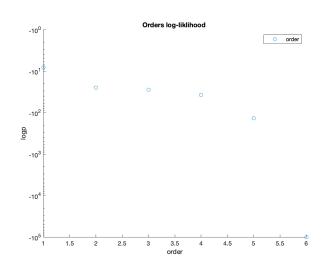

Covariance $3 = [4 \ 10; 1 \ 16].$

Covariance $4) = [2 \ 1; 1 \ 7].$

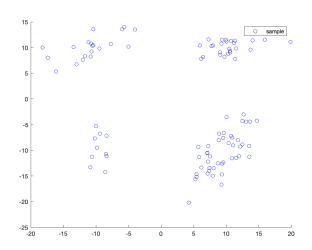

The gaussian model is selected of a larger value in such a way that they are widely separated from each other to reflect that they are separated from each other. Moreover, the K algorithm means once it's run the groups are defined, any new data can be easily assigned to the correct group. Given in end we get the cluster that is visible in each of the GMM distribution of each sample.

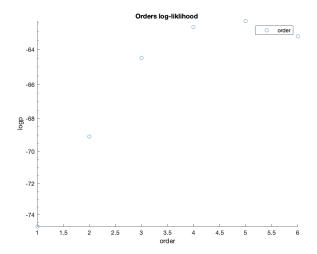

For N=10 the GMM data generated as below

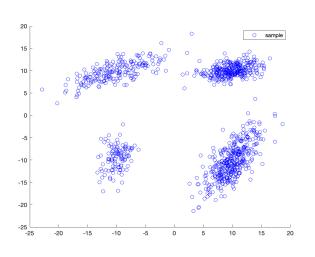

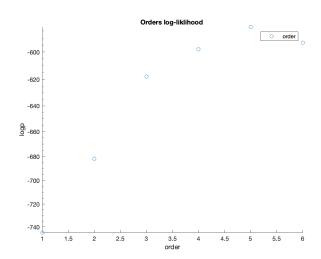

For N=100

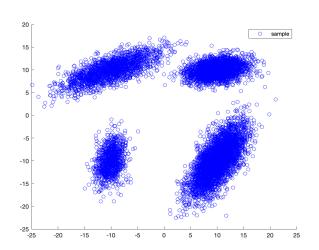

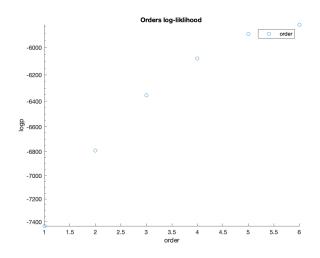

For N=1000

For N=10000

Conclusion:

The log likelihood indicates number of components =4 is a good model for this data. After the component 6 it stops. Moreover, at component=4 the graph quickly plateaus around the 4. Hence, we can consider it the best component for this gaussian mixture model.

As we see for the 10 to 100 samples the graph does not plateaus but from 1000 it starts to come becomes contact till the 6 point and when samples are increased it start to flatten and becomes constant from the 4th component.

Appendix:
